FOR OFFICIAL USE ONLY

The present invention relates to a client-server distributed computer system. Such a computer system has application in broadcast multimedia applications.

Early computer systems were standalone systems, consisting generally of mainframe computers. Later, several mainframe computer systems were closely connected, or clustered, to handle larger computing jobs, such as a large number of time sharing users. With the advent of personal computers, large numbers of relatively low power standalone computer systems were controlled directly by their users. Soon these large numbers of personal computers were coupled together into networks of computers, providing shared resources and communications capabilities to the users of the individual personal computers and between those users and the preexisting mainframe computers.

One form of such a network includes a central computer, called a server, which generally includes a large amount of mass storage. Programs used by the network users are centrally stored in the mass storage on the server. When a user desires to run a program, the user's computer requests that a copy of that program be sent to it from the server. In response to that request, the server transfers a copy of the program from its mass storage to the main memory of the personal computer of that user, and the program executes on that personal computer. Data also may be centrally stored in the server and shared by all the users on the network. The data is stored on the mass storage of the server, and is accessible by all the network users in response to a request. The server also serves as a hub for communications of messages (electronic mail) between network users. The server in such a system handles the storage and distribution of the programs, data and messages, but does not contribute any processing power to the actual computing tasks of any of the users. I.e. a user cannot expect the server computer to perform any of the processing tasks of the program executing on the personal computer. While such networks perform a valuable function, they are not distributed computing systems, in which interconnected computers cooperate to perform a single computing task.

In an improvement to such networks, the network may be configured in such a manner that a user on the network may request that the server, or other personal computer connected to the network, execute a program. This is termed remote execution because a computer (server or other personal computer) remote from the requester is executing a program in response to a request from the requester. In such a system, the program of which remote execution is requested is either sent from the requester to the remote computer, or retrieved from the server in response to a request by the remote computer. When the program is received, it is executed. In this manner several computers may be enlisted to cooperate in performing a computing function.

Recently, there have been programs which distribute the actual computing tasks necessary for performing a single computing function. For example, in such a data base program, where the data base is stored in the mass storage of the server, if a user desires to make a query of the data base, the portion of the data base management program on that user's personal computer will generate a query request, which is forwarded to the server. The portion of the data base management program on the server performs the query processing, e.g. parsing the query request, locating where the data specified in the query request resides on its mass

SUB  
C107

In accordance with principles of the present invention, a distributed computer system comprises a source of a continuous data stream repetitively including data representing a distributed computing application and a client computer, 15 receiving the data stream, for extracting the distributed computing application representative data from the data stream, and executing the extracted distributed computing application.

In a distributed computing system according to the invention, the client computer system need not include all the resources, in particular, main memory and mass storage, necessary to perform the entire program. Instead, no mass storage is required because the data stream provides the function of the mass storage device, and the main memory requirement is modest because only the currently executing portion of the program need be stored in memory. When the currently executing portion has completed, its memory space is freed up, and the next executing portion is extracted from the data stream, stored in the freed memory space, and that portion begins execution.

In addition, a distributed computing system according to the present invention allows the user of the client computer to have the option participating in the distributed computing task. If it is desired to participate, the client computer extracts the data representing the distributed computing application and executes the distributed computing application, as described above. If it is desired not to participate, the data stream is merely ignored, and the processing desired by the user, or none at all, is performed. Such a distributed computing system also allows each participating client computer to join the distributed computing function at any time and to proceed at its own pace in performing its own computing function.

A distributed computing system according to the present invention is particularly amenable to interactive TV applications because it allows a viewer to tune into an interactive TV channel at any time, join in the interactivity whenever desired (or not at all), and allows all the viewers to proceed at their different paces. This is especially advantageous in an environment when an interactive commercial, with its own executable code and data, may be presented within an interactive program, or when the viewer wishes to change channels.

In the drawing:

FIG. 1 is a block diagram of a distributed computing system according to the present invention;

FIG. 2 is a block diagram of a server computer as illustrated in FIG. 1;

FIG. 3 is a timing diagram illustrating the data streams 60 produced by a server computer in a distributed computing system as illustrated in FIG. 1;

FIG. 4 is a block diagram of a client computer as illustrated in FIG. 1.

FIG. 1 is a block diagram of a distributed computing system according to the present invention. In FIG. 1, a server computer 10, which may include a large computer system,

40

50

60

Any of the client computers 20 may join the distributed computing function represented by the packet stream at any time, and each of the client computers 20 may operate at its own speed, generally in response to the user 80. In order to

Furthermore, time code data may be included in either or both of the television auxiliary packet data stream and the packet data stream representing the interactive TV application. This permits synchronization of any graphic images or sounds generated by the client computer 22 with the television receiver or speakers.

In such an interactive TV system, both the client computer 22 and the auxiliary data processor 50 may be contained in a single enclosure, such as a television receiver, or television set-top decoder box. A television receiver, or decoder box would include connectors for attaching to a local computer or other equipment.

The user 80 provides input to the program running on the client computer 22 during its execution. This data may be required by the server 10 in order to effect the distributed computing function. In an interactive TV system, for example, user 80 may provide input to the client computer 15 through a handheld remote control unit.

The user data is transferred to the server computer 10 via the central processing facility 60. In one embodiment, data is sent from the client computers 20 to the server computer 10 via modems through the telephone system acting as the 20 central processing facility 60. The server computer 10 receives and processes the data received from the client computers 20 during execution of its portion of the distributed computing function.

Server computer 10 may generate new, or modify 25 existing, code and/or data modules in the data stream on the transport mechanism 30, in a manner described below, based on that received data. Alternatively, the server computer 10 may immediately return information to the client computers 20 in the other direction through the central processing 30 facility 60. The information in newly generated code and/or data modules is processed by all client computers 20 participating in the distributed computing function, while information passed from the server computer 10 to the client computers 20 through the central processing facility 60 is 35 specifically related to the client computer (22, 24, 26) to which that information was sent.

In another embodiment, the central processing facility 60 may include its own computer system, separately connected by modem to both the client computers 20 and the server 40 computer 10 through the telephone system. In either of the above embodiments, the central computing facility 60 provides access to other computers or processing facilities (not shown) via the telephone system. Thus, if information from other computer systems is needed to perform the distributed 45 computing function, those computer systems may be accessed via modem through the telephone system by either the client computers 20 or the server computer 10.

An input/output (I/O) port on the client computer 22 is coupled to a corresponding port on the local computer 40. Local computer 40 is collocated with the client computer 22. Local computer 40 may be a personal computer used by the user 80 of the client computer 22, or may be a larger computer, or computer network located at the same site as the client computer 22. This allows the client computer 22 to access data on the attached mass storage 70 of the personal computer or a computer on the network located at the client computer 22 site. In addition, the client computer 22 may use the mass storage 70 of the local computer 40 for storage of data to be retrieved later. It is likely that the local computer 40 will include both an output device (not shown) such as a computer monitor and an input device (also not shown) such as a computer keyboard. Both of these may be shared with the client computer 22 and/or the auxiliary data processor 50, as described above.

For example, the distributed computing system illustrated in may be part of a widespread corporate computing

SUB  
C127

system, and the server 10 may be located at a central location of that corporation. The client computer 22 may be located at a remote location, and the local computer 40 may be coupled to the personal computer network at that location. Workers at that location may store shared data (e.g. financial information) on the server connected to that network. The distributed computing function may include gathering local financial data from the client computers at the remote locations, processing that financial data and returning overall financial results to the client computers. In such an application, the executable code executing on the client computer 22 accesses the data from the local computer 40 (either from its attached mass storage 70 or through the network) through the I/O port, and sends it to the server computer 10 through the central processing facility 60. The server computer 10 continues its processing based on the information received from client computer 22 (and other client computers 20), and returns the results of that processing to the client computers 20 either through the central processing facility 60 or via the data stream on the transport mechanism 30.

In another example, the distributed computing system may be an interactive television system, broadcasting a home shopping show as the distributed computing application. In such a case, the auxiliary data carries the video and audio portion of the television signal, which may show and describe the items being offered for sale, and may include both live actors and overlaid graphics generated at the central studio. Code and data modules making up the interactive television application may include data about the products which will be offered for sale during this show, or portion of the show, and executable code to interact with the user in the manner described below.

When a viewer wishes to order an item, a button is pressed on the TV remote control. This button signals the client computer 22 to display a series of instructions and menus necessary to solicit the information necessary to place the order, e.g. the item number, name and address of the viewer, the method of payment, the credit card number (if needed), etc. These instructions are generated in the client computer as graphics which are overlaid on the television video image. It is also possible for a computer generated voice to be generated and combined with the television audio either by voice-over, or by replacing the television audio. The viewer responds to the instruction by providing the requested information via the TV remote control. When the information requested by the on-screen display and/or voice instructions has been entered by the viewer, it is sent to a central computer via the modem in the client computer. An order confirmation may be sent in the other direction from the central computer.

It is also possible that permanent information about the viewer (i.e. the name, address, method of payment and credit card number) may be preentered once by the viewer, so it is not necessary to solicit that information each time an order is placed. The information is stored in permanent memory in the client computer. In such a case, when an order is placed, that information is retrieved from the permanent memory, appended to the item number and transmitted to the central computer. It is further possible that, by means of time codes, or other commands, inserted into the data stream, the client computer will know which item is currently being offered for sale. In such a case, the viewer will be able to order it by simply pressing one button on the TV remote control. In response, the client computer can combine the previously received information related to the item currently being offered for sale with the previously stored personal infor-

C12  
Contd ->

0022660340926600

mation related to the viewer, and transmit the order to the central computer and receive the confirmation in return.

Because the code and data modules related to the home shopping program are repetitively inserted into the data stream, a viewer may tune into the program at any time and be able to participate interactively. Similarly, it is not necessary for the viewer to participate interactively, but may simply ignore the interactive portion of the show.

It is also possible for the client computer 22 to receive control information from the local computer 40. For example, the user 80, using the local computer 40, could control the client computer 22 via the I/O port to select a desired one of the data streams on transport mechanism 30, and process the program currently being broadcast on that data stream, with interaction with the user 80 through the input and output devices (not shown) connected to the local computer 40.

It is further possible for the user 80 to cause the client computer 22 to access the server computer 10 through the central processing facility 60, instead of via the data stream on transport mechanism 30, and receive code and data modules via this bidirectional link.

FIG. 2 is a block diagram illustrating a server computer 10 as illustrated in FIG. 1. In FIG. 2, a source of distributed computing application code and data 101 includes an application compiler, and software management module (not shown) and has an output terminal coupled to an input terminal of a flow builder 102. An output terminal of flow builder 102 is coupled to an input terminal of a transport packetizer 104. An output terminal of transport packetizer 104 is coupled to a first input terminal of a packet multiplexer 106. An output terminal of packet multiplexer 106 is coupled to an input terminal of a transport multiplexer 110. An output terminal of transport multiplexer 110 is coupled to the physical medium making up the transport mechanism 30 (of FIG. 1). A second input terminal of packet multiplexer 106 is coupled to a source of auxiliary data packets 107. A clock 109 has respective output terminals coupled to corresponding input terminals of the transport packetizer 104 and auxiliary data source 107. A data transceiver 103 has a first bidirectional terminal coupled to the central processing facility 60 (of FIG. 1) and a second bidirectional data coupled to the application code and data source 101. Application code and data source 101, flow builder 102, transport packetizer 104, auxiliary data source 107, clock 109 and packet multiplexer 106, in combination, form a channel source 108 for the transport mechanism, illustrated by a dashed box in. Other channel sources, including similar components as those illustrated in channel source 108 but not shown in FIG. 1, are represented by another dashed box 108a. The other channel sources (108a) have output terminals coupled to other input terminals of the transport multiplexer 110, and may have input terminals coupled to central processing facilities through data transceivers.

In operation, data representing the distributed computing application program, and data related to the transmission of the program over the transport mechanism 30 are supplied to the flow builder 102 from the application source 101. This data may be supplied either in the form of files containing data representing the code and data modules, or by scripts providing information on how to construct the code and data modules, or other such information. The code and data modules may be constant or may change dynamically, based on inputs received from the client computers 20 via the central computing facility 60 and/or other sources. The executable code and data module files may be generated by a compiler, interpreter or assembler in a known manner in

0022604252600

2

1

2

4

6

application compiler. These amended files are then processed by the flow builder again to generate another flow. It is further possible that the code and data files in the application source 101 may be amended automatically and dynamically (i.e. in real time) in response to data received 5 from the transceiver 103, and the flow updated as the data is being received from the client computers 20.

FIG. 3 is a timing diagram illustrating the data streams produced by the server computer 10 in a distributed computing system as illustrated in FIG. 1. In FIG. 3 server 10 computer 10 is shown as simultaneously producing a plurality of packet streams 32-38. Each packet stream (32-38) is shown as a horizontal band divided into packets having the same duration and number of bits. As described above, it is possible that the size of the packets within any packet 15 stream vary with the amount of data to be carried. In FIG. 3 it can be seen that the starting times of the packets are not synchronized. It is possible to synchronize the packets, but it is not necessary. In FIG. 3, packets carrying data representing directories are designated DIR, packets carrying data 20 representing code modules are designated CM, packets carrying data representing data modules are designated DM, and packets carrying auxiliary data are designated AUX.

In the top series of packets 32, the leftmost packet contains data representing a code module, CM. This is 25 followed by three packets containing auxiliary data, AUX, followed by another packet containing data representing the code module, CM. From the series of packets 32 it can be seen that the code module is repetitively produced. There may be more or fewer packets in between successive repetitions of the code module packets CM. The rate of repetition may be specified by the programmer when the application is programmed, and may be varied during the execution of the application. 30

In the next series of packets 34, the leftmost packet 35 contains auxiliary data, AUX. The next two packets contain respective portions of a code module (CM1,CM2). The last packet contains auxiliary data, AUX. From the series of packets 34 it can be seen that if a code module is too large to be contained in a single packet, it may be carried by more 40 than one, with each packet containing a portion of the code module. Although two packets are illustrated in the series of packets 34 as containing the code module (CM1,CM2), any number of packets may be used to carry the code module, depending upon its size. The two packets carrying the code 45 module, (CM1,CM2) are repetitively transmitted (not shown) in the series of packets 34, as described above.

In the series of packets 36, the leftmost packet contains data representing a code module (CM). The next packet (DM1) is a first packet containing data representing a data 50 module. The next packet contains auxiliary data, AUX. The next packet (DM2) is a second packet containing the remaining data representing the data module. From the series of packets 36 it may be seen that a data module (DM1,DM2), associated with the code module (CM), may also be included 55 in the packet stream. Both the code module (CM) and the data module (DM1,DM2) are repetitively transmitted (not shown) in the series of packets 36. The rate of repetition of the code module (CM) may be different from that of the data module (DM1,DM2), and both rates may be specified by the 60 application programmer and varied during the execution of the application.

It may further be seen that if the data module is too large to be contained in a single packet, it may be carried by more than one packet, with each packet containing a portion of the 65 data module. Although two packets are illustrated in the series of packets 36 as containing the data module (DM1,

00226046526700

DM2), any number of packets may be used to carry the data module, depending upon its size. It may be further seen that the packets carrying the data module need not be transmitted sequentially, but may have intervening packets in the packet stream. The same is true for multiple packets carrying a code module or directory module (not shown).

In the bottommost series of packets 38, the leftmost packet contains data representing the directory (DIR). The next packet contains data representing a code module (CM), followed by a packet containing auxiliary data (AUX) and a packet containing data representing a data module (DM). In the series of packet 38 all of a directory module (DIR), a code module (CM) and a data module (DM) in a single packet stream may be seen. The respective repetition rates of these three modules may be different, as specified by the programmer of the application, and may be varied during the execution of the application.

FIG. 4 is a block diagram of a client computer 22 as illustrated in FIG. 1. In FIG. 4, transport mechanism 30 (of FIG. 1) is coupled to an input terminal of a stream selector 202. An output terminal of stream selector 202 is coupled to respective input terminals of an auxiliary data extractor 204 and a packet data extractor 206. An output terminal of auxiliary data extractor 204 is coupled to the auxiliary data processor 50 (of FIG. 1). A bidirectional terminal of packet data extractor 206 is coupled to a corresponding terminal of a stream I/O adapter 208. A control output terminal of stream I/O adapter 208 is coupled to a corresponding control input terminal of stream selector 202. The combination of stream selector 202, auxiliary data extractor 204 and packet data extractor 206 form a data stream receiver 207 for client computer 22, illustrated by a dashed line in FIG. 4.

Stream I/O adapter 208 forms a part of a processing unit 224 in client computer 22, illustrated by a dashed line in FIG. 4. In addition to the stream I/O adapter 208, processing unit 224 includes a processor 210, read/write memory (RAM) 212 and read-only memory (ROM) 214 coupled together in a known manner via a system bus 216. Further input and output facilities are provided by an I/O port 218, coupled to the local processor 40 (of FIG. 1); user I/O adapter 220, for communicating with user 80; and modem 222, coupled to the central processing facility 60 (of FIG. 1); all also coupled to the system bus 216 in a known manner. Other adapters (not shown) may be coupled to system bus 216 to provide other capabilities to the processing unit 224.

As described above, auxiliary data extractor 204, I/O port 218 and modem 222 are not required in a client computer 20 according to the present invention. They are illustrated in FIG. 1 and FIG. 4 to show optional additional functionality.

In operation, processor 210 of processing unit 224 retrieves program instructions permanently stored in ROM 214, or temporarily stored in RAM 212, and executes the retrieved instructions to read data from ROM 212 and/or RAM 214, write data to RAM 212 and/or receive data from or supply data to outside sources via the I/O port 218, user I/O adapter 220 and/or modem 222, in a known manner. Under program control, processor 210 may also request a code and/or data module from the data stream supplied to the client computer 22 via the transport mechanism 30 (of FIG. 1). To retrieve this data, processor 210 first instructs stream I/O adapter 208 to send a selection control signal to the stream selector 202, possibly in response to user input from user I/O adapter 220. Then processor 210 issues a request for a specific code or data module to the stream I/O adapter 208. Stream I/O adapter 208 relays this request to the packet data extractor 204.

Transport mechanism 30 (of FIG. 1) supplies all of the plurality of packet streams (32-38 of ) it carries to the

00226042639600

An interactive TV system, may also include a sound adapter coupled to the system bus 216. The sound adapter 65 generates a signal representing a computer generated sound (such as music, synthesized voice or other sound), in a

5. The distributed computer system of claim 1 wherein said further processor includes memory for storing program controls and responsive thereto requests of said packet selector a code and/or data module from the data stream.

a source of a time division multiplexed packet signal including a plurality of distributed computing applications, each distributed computing application 10 being repetitively transmitted independent of receiving client computer apparatus, and each of said distributed computing applications being in a form of a series of packets;

a second one of packets of the series contains data representing a data module and includes identification information indicating that said second one of packets contains data representing the data module; and

a client computer including a data receiver for selecting packets of one of the plurality of distributed computing applications, and extracting the corresponding distributed computing application representative data included in the selected packets and applying it to computer program controlled apparatus for executing the extracted distributed computing application, said data receiver extracting auxiliary data from auxiliary packets in the data stream and supplying it to an auxiliary data processor.

a data stream source producing a data stream including a series of packets representing a plurality of time division multiplexed signals, one of said signals including data representing a distributed computing application, which distributed computing application is repetitively transmitted independent of receiving client computer apparatus, and at least one of the packets of the signal representing the distributed computing application includes a directory module containing information inter-relating packets associated with said distributed computing application;

the client computer extracts said directory module from the data stream and using data contained in the directory module extracts packets associated with said distributed computing application and builds said distributed computing application and executes said distributed computing application.

a first one of the series of packets contains data representing an executable code module and includes iden-

5 a second one of the series of packets contains data representing a data module and includes identification information indicating that the second one of the series of packets contains data representing a data module;

10 a third one of the series of packets contains data representing said directory module inter-relating respective transmitted modules associated with a single distributed computing application, and includes identification information indicating that the third one of the series of packets contains data representing said directory module; and

15 a fourth one of the series of packets contains auxiliary data and includes identification information indicating that the fourth one of the series of packets contains auxiliary data.

an input terminal for receiving a packet data stream including packets of video signal time multiplexed with packets of data representing a distributed computing application which distributed computing application is repetitively transmitted independently of said client computer and at least one of the packets representing the distributed computing application includes a directory containing information inter-relating ones of the packets containing said distributed computing application;

a processing unit, coupled to the data stream receiver, for assembling said distributed computing application and executing the distributed computing application comprising:

read/write memory, coupled to the system bus;

a processor, coupled to the system bus, for controlling the data stream input/output device to generate a selection control signal selecting a specified one of the plurality of data streams, and for assembling and executing the distributed computing application stored in the read/write memory.
